Abstract

The field of information and computer security is rapidly developing in today's world as the number of security risks is continuously being explored every day. The moment a new software or a product is launched in the market, a new exploit or vulnerability is exposed and is exploited by the attackers or malicious users for different motives. Many attacks are distributed in nature and carried out by botnets that cause widespread disruption of network activity by carrying out DDoS (Distributed Denial of Service) attacks, email spamming, click fraud, information and identity theft, virtual deceit and distributed resource usage for cryptocurrency mining.

Botnet detection is still an active area of research as no single technique is available that can detect the entire ecosystem of a botnet like Neris, Rbot, and Virut. They tend to have different configurations and heavily armoured by malware writers to evade detection systems by employing sophisticated evasion techniques.

This report provides a detailed overview of a botnet and its characteristics and the existing work that is done in the domain of botnet detection. The study aims to evaluate the preprocessing techniques like variance thresholding and one-hot encoding to clean the botnet dataset and feature selection technique like filter and wrapper to boost the machine learning model performance.

In this paper, performance of network dataset has been compared to predict the accuracy and anomalies on the network. The machine learning algorithms which have been used here is Random Forest, Extra Trees, Logistic Regression and Multinomial Naïve Bayes. Our experiments show, that our approach can compare the useful traffic and the junk traffic effectively and reaches the accuracy of 79.21%. Lastly, the optimal model is found by testing each model on the dataset of attacks and comparing its performance.

Keywords - Botnet Detection, Feature Selection, Variance Thresholding

Introduction

The internet is plagued with information theft and security risks. Information theft includes personal details stolen to conduct identity fraud, and debit and credit card credentials traded on the dark web to carry out illicit transactions. Some of the security risks include but are not limited to systems, servers, and networks compromised with malware, trojan horses, phishing, ad-wares, and viruses. While accessing resources like audio, video, and images and surfing the internet, users are targeted with unwanted ads, spam notification, and emails and denial of service. The attacks mentioned are carried out in a distributed manner for

illegal purposes, monetary gains, to create biasedness among public opinion and harm the organization's reputation. comprises 32% of the attacks on the internet in the modern world. These nefarious activities are well organized and carried out by a hacker. A botnet is a network of malware compromised computers (called as bot or zombie) under the control of a hacker (also called as bot-herder or botmaster). A botherder controls the bots by using a Command-and-Control server (C&C). Identifying the vulnerable systems, propagating the malware, sending the command, and code updates and carrying out the attack are primarily controlled by the C&C server. A collective effort from the

botnet attacks can result in Distributed Denial of Service (DDoS), phishing, spamming, spreading of malware, information theft, unwanted ads, generating virtual clicks and cryptocurrency mining. Prevention or detection of botnet attack is difficult because of its inherent nature of changing the attacks modus operandi. Many types of research have been done to effectively and successfully detect and block botnet attacks. The goal of this project is to propose a machine learning model to detect botnets using machine learning with better precision and reduce false positives by studying existing work done in the botnet detection area. The articles selected for this project include conference proceedings, articles published papers.

This project tries to answer the following questions:

- 1. How the dataset imbalance issue of botnet originated traffic can be handled?
- 2. Is there any machine learning model that can detect a range of botnet attacks?

Literature Review

In the realm of cybersecurity, the detection and mitigation of botnets pose significant challenges, necessitating the exploration of effective machine learning algorithms. Ensemble methods, such as random forest, have shown promise in handling large-scale problems, with "[2] A Random Forest Guide Tour" emphasizing its versatility and performance in diverse learning tasks. Another ensemble method, "[4] Extremely randomized trees," presents a unique approach with fully random split points, potentially offering advantages in botnet detection scenarios. Statistical models like logistic regression and Bayesian classification methods scrutinized in "[3] Statistical comparison of logistic regression and different bayes classification methods for machine learning," evaluating their efficacy in identifying botnets.

Surveys like "[8] A Survey of Botnet and Botnet Detection Methods" provide a comprehensive overview, exploring various detection approaches, including honeynetbased solutions. "[9] A Survey on Botnets, Issues, Threats, Methods, Detection and Prevention" delves into the role of machinebased learning, specifically Auto-Encoders, in addressing botnet challenges. Studies "[13] Machine learning DDoS detection for consumer internet of things" and "[14] A flow-based botnet detection supervised machine learning" propose ML algorithms, including neural networks, for detecting DDoS attacks and distinguishing botnet traffic, respectively.

Network-based approaches, such as "[11] Network-based detection of IoT botnet attacks," leverage deep autoencoders to identify anomalous traffic from compromised IoT devices. **Temporal** evolution tracking, as explored in "[12] Tracking temporal evolution of network activity for botnet detection," addresses the challenge of evolving botnets, while "[15] botnet membership Revealing DNSBL counter-intelligence" investigates blackhole list (DNSBL) DNS-based lookups for effective botnet membership identification. In conclusion, this literature survey, incorporating papers [2], [3], [4], [8], [9], [13], [14], [11], [12], and [15], highlights diverse ML approaches for botnet detection, paving the way for a deeper understanding of their strengths, weaknesses, and potential areas for further research.

Data Collection and Analysis

For successful detection of a botnet in real-time, it is necessary to first build a detection model in a test environment before deploying it for real-time applications. Most of the dataset available for botnet detection suffers from the problem like traffic obtained from simulated environment and creation of fake traffic that does not reflect real-time traffic. The main aim in botnet detection would be to have a real-time, not simulated one.

SDN Dataset

The SDN Dataset is a Botnet Traffic Dataset that was captured in September 2020. It is a Dataset which consists of Botnets and Normal Flow Packets.

The Simulation starts by creating ten topologies in mini-net in which switches are connected to single Ryu controller. Network simulation runs for benign TCP, UDP and ICMP traffic and malicious traffic which is the collection of TCP Syn attack, UDP Flood attack, ICMP attack.

A normal packet is a traffic that corresponds to traffic created by a naive user like opening mail inbox, surfing social media websites and scouring the internet for online resources.

A Botnet packet is a traffic that corresponds to traffic created by a malicious user like DDoS Attack, Spam E-Mails or malware spreading codes.

Table 1: Dataset Diversity Distribution

Descriptive Analytics

The SDN dataset has total records of 104300 records out of which 60.91% traffic is normal traffic and 39.08% is botnet traffic. The distribution of traffic is shown in Figure 1 and it shows a significant balance that is present in the dataset. Protocol feature has 80.4% traffic using UDP protocol, followed by 18% of TCP protocol and 34% of ICMP protocol. The distribution of protocol is shown in Figure 2. The direction of the traffic was mainly bidirectional of 77.6 % followed by unidirectional with 21.8%.

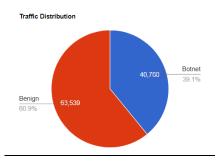

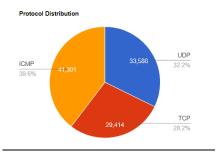

Figure 2: Protocol Distribution

Research Methodology

The field of machine learning is now the most widely implemented and experimented area. [10 – 15] have described various techniques of botnet detection using machine learning in combination with botnet characteristics. Botnet detection using machine learning techniques like Ramdom Forest (RF), Extra Trees (ET), Logistic Regression (LR), and

Multinomial Naïve Bayes model based on DNS Query data is mentioned in [10]. Bots of the botnet receive code and commands from the C&C server by performing lookup queries generated using DGA or fast-flux. [10] identifies that the IP address of the C&C server is not a legit name and keeps on randomly changing to avoid detection. Also, the generated malicious domain names have characteristics like DNS, network, and lexical features entirely different from benign domain names. [10] approaches to solve the problem by collecting 16 vocabulary features from 2-g and 3-g clusters like mean, variance, standard deviation, entropy, consonants, vowels. number. and character characteristics and 2 characteristics from vowel distribution. IP addresses are random with datasets generated from Conficker, and DGA botnet (malicious) and top domain names from Alexa Internet (benign) (collection of domain names) conjunction with machine learning models, [10] demonstrated the effectiveness of Random Forest machine learning model by delivering an accuracy of 98.71% in botnet detection.

Some related research papers to [10], [16] implemented techniques for detecting botnets on changing the IP addresses and it was successful in detecting traffic with many queries and terminated domains. Botnet detection models in the works of literature are heavily built for network and network devices as discussed in [10, 16, 17]. [14] considers Random Forest, Extra Trees, Logistic Regression and MNB and train these models on network flow parameters like length of the packet, size of the interval and protocol used. The detection pipeline is flow-based, uses either stateless or stateful features and is protocolagnostic. [14] expresses the surrounding IoT devices like lightweight

Figure 3: Conceptual Map of Project

characteristics, limited memory, computation power. Steps involved in building an IoT-based detection model is capturing the traffic, grouping the packets based on device and by time, extracting stateful and stateless features followed by a binary classification. [14] experimented with the dataset and found out that normal traffic packet size varies between 100 to 1200 bytes whereas attack traffic is under 100 bytes owing to repeated attacks. Also, the attack traffic has a lesser inter-packet interval in comparison to normal traffic. Most of the time protocols used during attack were TCP as opposed to UDP during normal situations. The classifiers were able to obtain training accuracy from 0.91 to 0.99. However, though the accuracy was 0.99, it was built on simulated data generated using DDoS network trafficbased botnet detection using machine learning. [14] predicts the model might be overfitting the data but is unsure of its performance on real-time attacks which opens the door for future research in the detection of botnets. Work was done in [11, 14] that focused on detecting botnet using IP address details and traffic flow characteristic, respectively.

On the other hand [16] focusses on leveraging the detection of botnet using an efficient flow-based technique by reducing the packet size and time of traffic flow under consideration. The model was developed to detect two P2P botnets namely Storm and Waledac botnets during the honeynet project. It has been noted in many papers that modern botnets are resilient to detection by employing techniques like obfuscation. protocols encrypted communication, fast-flux and random domain name generation using DGA. P2P botnets have a disastrous effect on industrial systems and their infrastructures. In order to train the models, [16] captured network traffic of five tuples like source IP

address, source port, destination IP address, destination port and protocol used. As well for every traffic, 20 other statistical features were extracted. [16] employed batch analysis and limited analysis of the captured traffic by using eight different machine learning algorithms like Naïve Bayesian Classifier (NB), Logistic Regression (LR), Random Forest Classifier and Extra Trees Classifier. In the modelling process of botnet detection of [16], all MLA delivered impressive performance except Naïve Bayesian Classifier for both malicious as well as non-malicious traffic. The tree classifiers delivered promising classification performance, but Random Forest Classifier delivered the highest accuracy. Remaining MLAs experimented in [16], delivered poor performance for non-malicious traffic as compared to normal traffic since the dataset was skewed in the former case. Also, the initial 10 packets per flow are evident enough to detect botnet as opposed to monitoring the entire flow.

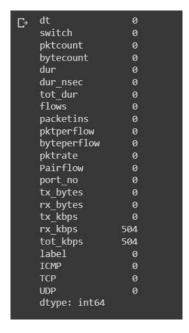

To summarize, [14] experimented with detecting botnet on consumer internet of device-based thing attack. Γ14**1** demonstrated the effectiveness of (MNB), Logistic Regression (LR), Extra Trees and Random Forest by achieving an average accuracy of 87%. [14] also considered stateful features like bandwidth, and IP destination address cardinality and novelty and stateless features like packet size, interpacket interval and protocols separately and together during the training phase. [15] employed flow-based machine learning technique for botnet detection experimented with models like Naïve Bayes, Bayesian Net, Artificial Neural Network. Support Vector Machine. Random Tree, Random Forest, Decision Tree. The flow-based model was able to achieve accurate detection of traffic.

Experimental Results

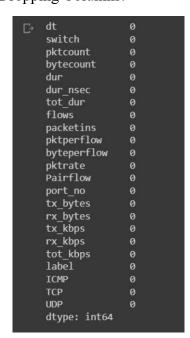

1. Preprocessing Data

We have Dropped the unnecessary columns such as 'Source' and 'Destination'.

Before Dropping Columns:

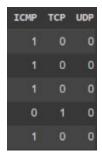

After Dropping Columns:

We have performed one-hot encoding on the column 'Protocol' to classify the categorical variable into a numerical format. Before One-Hot Encoding:

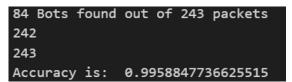

After One-Hot Encoding:

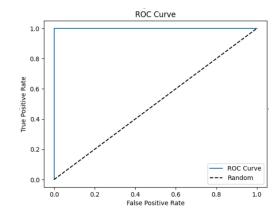

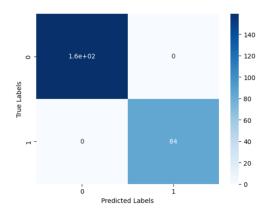

2. Random Forest

Random forest is an ensemble learning method that combines multiple decision trees to make predictions. Each decision tree in the random forest is built independently on a randomly sampled subset of the training data. The final prediction is obtained by aggregating the predictions of all the individual trees.

AUC-ROC score: 1.0

3. Extra Trees

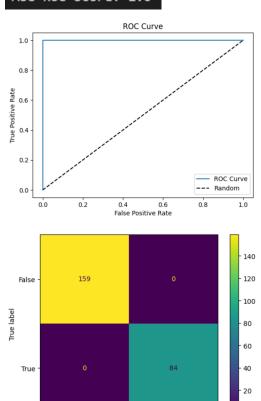

Extra Trees is a variation of the random forest algorithm that introduces additional randomness during the construction of individual decision trees. In random forests, the algorithm considers a subset of features at each split point to find the best split.

```
84 Bots found out of 243 packets

Predicted label

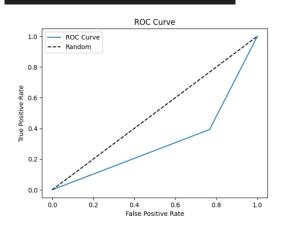

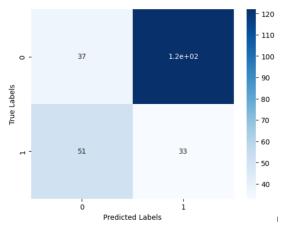

4. Logistic Regression

Logistic regression is widely used for binary classification, where the goal is to predict one of two possible classes based on input features. It can also be extended to handle multi-class classification problems through techniques like onevsrest or softmax regression.

```
33 Bots found out of 243 packets
70
243
Accuracy is: 0.2880658436213992
```

AUC-ROC score: 0.312780772686433

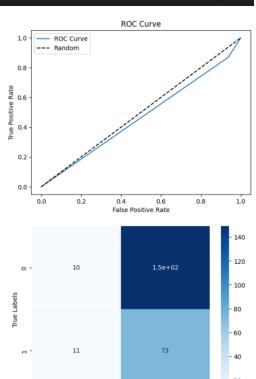

5. Multinomial Naïve Bayes

The multinomial naive Bayes algorithm is based on the principle of Bayes' theorem. It assumes that the features are conditionally independent given the class variable. It is called "naive" because it makes a strong assumption of feature

independence, which may not hold true in many real-world scenarios. However, despite its simplifying assumptions, multinomial naive Bayes often performs well in practice, particularly in text classification tasks.

```
73 Bots found out of 243 packets
83
243
Accuracy is: 0.34156378600823045
```

AUC-ROC score: 0.46597035040431267

Results

Our data was used in building four models namely extra trees, random forests, logistics regression and multionomial NB. We calculated the accuracy, AUC-ROC score and the confusion matrix. The accuracy turned out to be 100%, 99.58%, 60.62% and and 56.62%. The data tested contained 243 rows of the same 22 features. The AUC-ROC value calculated is 1, 0.99, 0.28 and 0.33 respectively.

Predicted Labels

Conclusion

This research study has demonstrated that Extra Trees and Random Forest algorithms outperform Multinomial Naive Bayes (NB) and Logistic Regression models in the context of botnet detection. Through a comprehensive evaluation and comparison, it has been established that both Extra Trees and Random Forest exhibit superior in terms of accuracy (99.95 and 99.98 of extra trees and random forests percent when compared to 56.62 and 60.66 percent of logistics and multinomial), AUC-ROC score, and a better confusion matrix.

Extra Trees and Random Forest models are particularly adept at handling high-dimensional feature spaces, which is essential in botnet detection where numerous network-based attributes need to be considered simultaneously. These algorithms automatically select informative features and mitigate the impact of irrelevant or noisy attributes, thereby enhancing their ability to accurately distinguish between normal network traffic and botnet activity.

The reason for failure of logistic regression assumes a linear relationship between the predictor variables and the log-odds of the outcome. If the relationship is non-linear, logistic regression may fail to capture complex patterns accurately. Also, when the predictor variables are highly correlated, logistic regression can struggle to provide reliable coefficient estimates. This scenario can lead to issues such as multicollinearity and unstable model performance.

Multinomial Naive Bayes (NB) is designed to handle discrete features, such as word frequencies or categorical variables. When applied to numeric-heavy data, Multinomial NB may encounter challenges or fail to provide accurate results. Multinomial NB operates on the assumption of discrete features with discrete probability distributions. When dealing with numeric data, it requires binning or discretization of the numeric values. This binning process can result in a loss of information and granularity in the data. The discretization process may not capture the underlying distribution of the numeric features accurately, leading to suboptimal results.

Moreover, the efficiency of Extra Trees and Random Forest algorithms enables real-time or near real-time botnet detection, which is crucial for timely response and mitigation. The parallelization capabilities and inherent scalability of these algorithms make them well-suited for processing large volumes

of network traffic data, thereby reducing detection latency and enhancing the overall effectiveness of botnet detection systems.

In conclusion, the results of this research highlight the superiority of Extra Trees and Random Forest algorithms over Multinomial NB and Logistic Regression for botnet detection. Their ability to handle complex patterns, high-dimensional data, imbalanced datasets, and their efficiency in real-time detection make them valuable tools for identifying and mitigating botnet activity in network environments. Future research can further explore the application of these algorithms in evolving botnet detection scenarios and investigate their potential for improving the accuracy and resilience of botnet detection systems.
